An Evidence-Based Endodontic Implant Algorithm: Back to the Egg; Concluding Part

Kenneth S. Serota, DDS, MMSc

A n increased uniform amount of coronal dentin significantly amplifies the fracture resistance of endodontically treated teeth, regardless of the post system used or the choice of material for the full-crown restoration. A recent article by Coppede et al demonstrated that friction-locking mechanisms and the solid design of internal conical abutments provided greater resistance to deformation and fracture under oblique compressive loading when compared to internal hex abutments. These two “seemingly” disparate observations define the inherent continuum between natural tooth engineering and the principles of engineering necessary to orthobiologically replicate the native state.

The use of a ferrule or collet and a bonded or intimately fit post-core to restore function and form to an endodontically treated tooth is analogous to the use of a long, tapered friction fit interface to secure an abutment to a tooth. The cone-screw abutment has been shown to diminish micro-movement by reducing the burden of component loosening and fracture. This enables the identification of the effects of the parameters such as friction, geometric properties of the screw, the taper angle, and the elastic properties of the materials on the mechanics of the system. In particular, a relation between the tightening torque and the screw pretension is identified. It was shown that the loosening torque is smaller than the tightening torque for typical values of the parameters. Most of the tightening load is carried by the tapered section of the abutment, and in certain combinations of the parameters, the pretension in the screw may become zero.

This enables the identification of the effects of the parameters such as friction, geometric properties of the screw, the taper angle, and the elastic properties of the materials on the mechanics of the system. In particular, a relation between the tightening torque and the screw pretension is identified. It was shown that the loosening torque is smaller than the tightening torque for typical values of the parameters. Most of the tightening load is carried by the tapered section of the abutment, and in certain combinations of the parameters, the pretension in the screw may become zero.

Future modifications to implant biomechanics should focus on designs wherein the osseous trabecular framework retaining the fixture will adapt to the amount and the direction of applied mechanical forces, cope with off-axis loading, compensate for osseal plane to implant height ratios differences as well as adjusting to mandibular flexion and torsion.

In this new era of implant driven treatment planning, fixtures should be engineered to support single crowns with canti-levers instead of implant/implant or implant/teeth connections for a span of any degree. These engineering design iterations will minimise high-stress torque load at the implant abutment interface and obviate areas with degrees of bone insufficiency.

The goal should be to biomimetically replicate the natural state to the greatest degree (Figures 10a and 10b) in regard to load bearing capacity. Measuring success Stable crestal bone levels are the yardstick by which treatment success and health are measured in the orodental ecosystem, whether it relates to natural tooth retention, restorative and/or replacement rehabilitation. It is therefore surprising that the treatment outcome standards for
osseointegration accept crestal bone remodeling and resorption of up to 1.5 - 2mm during the first year following fixture placement and prosthetic insertion 10.

The concept of “biological width” outlines the minimum soft tissue dimension that is physiologically necessary to protect and separate the osseous crest from a healthy gingival margin surrounding teeth and the peri-implant environment.

A bacteria-proof seal, the lack of micro-movement associated with a friction grip interface and a minimally invasive second-stage surgery (where indicated) without any major trauma to the periosteal tissues, are also important factors in preventing cervical bone loss. The literature suggests that the stability of the implant/abutment interface may have an important early role to play in determining crestal bone levels 11.

Platform switching: By default or by design

There is no logical way to the discovery of elemental laws. There is only the way of intuition, which is helped by a feeling for the order lying behind the appearance,” Albert Einstein.

Platform switching theorises that by using an abutment diameter of a lesser dimension than the periphery of the implant fixture, horizontal relocation of the implant-abutment connection will reduce remodeling and resorption of crestal bone after insertion and loading.

The concept implies that peri-implant hard tissue stability will engender soft tissue and papilla preservation. Maeda et al reported that stress levels in the cervical bone area peripheral to a fixture were reduced when a narrow diameter abutment was connected in comparison to a size commensurate with the fixture diameter 12.

The authors concluded that the biomechanical advantage of shifting stress concentrations away from the cervical area will diminish their impact on the biological dimension of hard and soft tissue extending apically from the FAI (Fig 11a, 11b and 11c).

The inherent disadvantage is that it shifts stress to the abutment screw with the potential for loosening or fracture.

Baggi et al detected neutrophilic infiltrate in the connective tissue zone contacting the implant-abutment interface. The facility by which platform switching/shifting reduces bone loss around implants has been investigated by Lazzara et al 13. The authors hypothesised, that if the abutment diameter matches that of the implant, the inflammatory cell infiltrate is formed in the connective tissue contacting the microgap created at the FAI.

If an abutment of narrower diameter is connected to wider neck implant, the FAI is shifted away from the outer edge of the implant, thus distancing inflammatory cell infiltrate away from bone. Hypothetically, less crestal bone loss is expected and an increased implant/abutment disparity allows more stable peri-implant soft tissue integration.

Type II bone quality was approximated and complete osseous integration was assumed. It was concluded that the Ankylos G/X implant based on its platform...
switched and subcrestally positioned design demonstrated better stress based performance and lower risk of bone overload than the other implant systems evaluated.

**Essential features**

Platform switching, together with a stable implant-abutment connection are increasingly accepted essential implant design features required to reduce or eliminate early crestal bone loss. A bacteria-proof seal, a lack of micro-motion due to a long friction grip tapered channel and minimally invasive second-stage surgery without any major trauma for the periosteal tissues are also important factors in preventing cervical bone loss.

A preconfigured platform switched design has a significant impact on the implant treatment in esthetic areas as not only is the tissue biotype preserved, but it has been shown to be enhanced by osseous generation over the collar of the fixture (Figs 12a and 12b).46

The endodontic implant algorithm parallels the question, which came first, the chicken or the egg as an example of circular cause and consequence. It could be reformulated as follows: ‘Which came first, X that can’t come without Y, or Y that can’t come without X?’ An equivalent situation arises in engineering and science known as circular reference, in which a parameter is required to calculate that parameter itself. This is the essence of foundational dentistry.

Nature wisely created a structure that could harmoniously interoperate hard and soft tissue, act as the portal of nutrition and communication for the body and be the gatekeeper on guard and in function through our lifetime. As such, our role is to ensure that however we reengineer nature, we must adhere to its rules, its logic and its fundamentals.

**The best evidence**

This is not an easy task, asfiltering out the best range of evidence from a wide range of sources, presenting clear, comprehensive analyses and incorporating patient experience is a Herculean task. In many ways, this is analogous to Alice’s Adventures in Wonderland as much of what we do grows ‘curiouser and curiouser’ as each new innovation demands that we go through the looking glass and determine what Alice found there.

About the author

Kenneth S Sonoda, DDS, MMSc graduated from the University of Toronto, Faculty of Dentistry in 1973 and was awarded the George W. Scriba Memorial Key for Excellence in Prostodontics. He received his Certificate in Endodontics and Master of Medical Sciences Degree from the Harvard Forsyth Dental Center in Boston, MA. The founder of ROOTS – an online educational forum for dentists from around the world who wish to learn cutting edge endodontic therapy, he recently launched IMPLANTS (www. implants.com) and www.ksonline.com in order to provide a clear understanding of the endodontic/implant algorithm in foundational dentistry.

‘There’s no use trying,’ said Alice. ‘One can’t believe impossible things.’ ‘I dare say you haven’t had much practice,’ said the Queen. ‘When I was your age, I always did it for half an hour a day. Why, sometimes I’ve believed as many as six impossible things before breakfast!’ Lewis Carroll.
